ADAM15; 1.85 ± 0.04 in RVF, 1.3 ± 0.14 in E2 for ADAM17. All normalized to resp. CTRL, all $p<0.05$). In vitro, E2 also reversed expression of these genes induced by Angiontensin II (2.74 ± 0.19 in AngII, 1.72 ± 0.01 in AngII+E2 for OPN; 1.31 ± 0.06 in AngII, 0.88 ± 0.02 in AngII+E2 for ADAM15; 1.55 ± 0.01 in AngII, 1.09 ± 0.002 in AngII+E2 for ADAM17. All normalized to resp. CTRL, all $p<0.05$). E2 therapy was associated with complete reversal of RV fibrosis and changes in OPN, ADAM15 and ADAM17 expression. This data indicates that E2 has a direct effect on mitigating the adverse remodeling of the RV during PH.

G-Protein Coupled Estrogen Receptor 1, but not Estrogen Receptors Alpha and Beta, Mediates Rapid Estrogen-Induced Cardioprotection during Ischemia/Reperfusion Injury in Male Mice

Jean C. Bopassa[1], Rong Lu[1], Harpreet Singh[1], Bjorn Olde[2], Andree Krust[3], L.M. Fredrik Leeb-Lundberg[2], Ligia Toro[1], Enrico Stefani[1].
[1]UCLA School of Medicine, Los Angeles, CA, USA, [2]Department of Experimental Medical Science, Lund University, 22184 Lund, Sweden, [3]Institut de Génétique et Biologie Moléculaire et Cellulaire 67404, Illkirch, France.

Mouse heart possesses three types of estrogen (E2) receptors, ERα, ERβ and the G-protein coupled estrogen receptor1 (GPER1). We previously reported that rapid E2-induced cardioprotection is abrogated in GPER1$^{-/-}$, and that this action is mediated by pERK1/2 and pGSK-3β stimulation in absence of pAkt increase.

Here, we investigated the potential role of ERα, and ERβ in mediating the rapid cardioprotective action of E2 in ischemia/reperfusion injury in male mice, and further corroborated the role ERK1/2 and GSK-3β without the participation PI3K/Akt pathway.

We first quantified mRNA absolute levels of the three receptors in heart, and found that ventricles express much higher levels of GPER1 than ERα and ERβ. E2 (40 nM) treatment in the Langendorff model of ischemia/reperfusion improved cardiac functional recovery, reduced infarct size, and increased calcium-retention-capacity (a measure of mitochondrial transition pore, mPTP, opening) to the same degree in WT, ERα$^{-/-}$ and ERβ$^{-/-}$, further confirming no role of ERα and ERβ in rapid E2-induced cardioprotection. As previously reported, these beneficial effects were completely abrogated in GPER1$^{-/-}$. The involvement of MAPK-ERK1/2 pathway is further supported by the loss of E2-induced increase of calcium-retention-capacity by treatment with U01261, an ERK1/2 pathway inhibitor. The rapid E2 action did not involve PI3K pathway as the E2-induced pGSK-3β high level was not affected by treatment with LY294002, a PI3K inhibitor.

In summary, in male mice, only GPER1 activation mediates the rapid E2-induced cardioprotection against ischemia/reperfusion injury via phosphorylation of ERK1/2 and GSK-3β leading to increased mitochondrial calcium-retention-capacity reflecting a reduction of mPTP opening. Supported by NIH and AHA.

The heart from a diabetic animal exhibits dysfunction when exposed to challenging energetic and tissue redox conditions. We showed that when cardiomyocytes from type-2 diabetes (db/db) mice are exposed to high glucose (HG) and β-adrenergic stimulation (via isoproterenol, ISO), these cells show blunted β-contractile reserve and increased oxidative stress. Treating these cells with the fatty acid (FA) palmitate (Palm) offsets those changes, an effect likely due to its ability of generating more reducing equivalents. Yet whether Palm infusion may benefit contractile performance and vascular tone of db/db hearts subjected to metabolic/redox stress is unclear. Using a Langendorff approach, we perfused wild type (WT) and db/db mice with HG (30mM glucose) + ISO (10nM), in absence or presence of Palm. WT hearts were infused with 0.2mM Palm and db/db ones with 0.4mM Palm to mimic higher circulating FA content in diabetic animals. Under HG, coronary perfusion pressure (CPP) was higher in db/db hearts (92 ± 8 vs. 63 ± 7 mmHg, $p<0.05$). This increase in tone was obviated by Palm. WT had better myocardial performance than db/db mice. For instance, dP/dtmax was 4653 ± 460 in WT vs 3474 ± 185 mmHg/sec in db/db ($p<0.05$). Although markedly blunted, ISO response was still present in db/db hearts (2821 ± 83 vs 3474 ± 185 mmHg/sec, $p<0.05$). However, HG fully blocked ISO-response. Infusing Palm to db/db preserved ISO response under HG (2392 ± 505 vs 3106 ± 425 mmHg/sec, $p<0.05$). Our study reveals that preferential FA oxidation improves heart LV function in diabetic mice subjected to combined energetic and redox challenge. This beneficial effect of Palm may be due to glucose-to-FA substrate shift and also to improved redox balance as shown in isolated cardiomyocytes.

Mathematical Model of Oxygen Labeling to Study Heart Energy Transfer

David W. Schryer, Pearu Peterson, Ardo Illaste, Marko Vendelin.
Laboratory of Systems Biology, Tallinn, Estonia.

The mechanisms underlying the homeostasis of ATP, ADP, PCr and inorganic phosphate in heart under a wide range of workloads remain unclear. Fundamental to this search is an accurate understanding of the recycling fluxes of these metabolites between the mitochondrial inner membrane space and the ATPases on both the myofibrils and SERCA pumps. In addition to ^{31}P-NMR inversion and saturation transfer studies, dynamic ^{18}O labeling data has been used to analyze energy transfer. An integrative kinetic model that tracks the mass isotopomers of these four metabolites was constructed with the following compartments: mitochondrial matrix, mitochondrial intermembrane space, cytosol, and enzyme bound states of both ATPase and ATP synthase (since these reactions are not unidirectional with respect to oxygen exchange). A sensitivity analysis of this system was conducted with a jump to 30% $H_2{}^{18}O$ to find flux parameters that influenced the ^{18}O labeling state. Both the creatine kinase and adenylate kinase shuttle fluxes were modeled as being bidirectional to test assumptions made in previous studies that analyzed dynamic ^{18}O labeling data.

It was found that the sum of forward and reverse fluxes through each shuttle determined the labeling state such that if the sum is kept constant and the net flux is reduced, a very similar labeling state is predicted. Total creatine kinase and adenylate kinase fluxes that exceeded the ATP synthase rate were also found to give almost the same predictions of the labeling state. Model predictions of the ^{18}O labeling state of metabolites are very similar using energy fluxes reported in earlier studies of ^{18}O labeling in the heart and energy transfer analysis by ^{31}P-NMR inversion and saturation transfer.

Oxygen Increases Heart Injury in Ischemia/Reperfusion

Jean C. Bopassa, Ligia Toro, Enrico Stefani.
UCLA School of Medicine, Los Angeles, CA, USA.

Mice hearts were perfused using Langendorff apparatus with Krebs-Henseleit (KH) buffer oxygenated with 95% O_2 + 5% CO_2 at 37°C. Hearts were maintained suspended in the air in the humid chamber at 37°C for 20 min. Thereafter, hearts were either immersed in KH or kept in air in the same chamber at 37 °C, and subjected to 18 min of global ischemia by clamping the aorta. Afterwards, hearts were returned to air in the same humid chamber for 40, 60 or 90 min reperfusion. Heart function was monitored and myocardial infarction assessed by TTC staining at the end of the reperfusion. ROS generation was measured with Amplex Red in mitochondria isolated after 10 min of reperfusion.

When the hearts were immersed in KH, heart function and infarct size had reached an injured steady-state at 40 min of reperfusion. In contrast, hearts kept in air had a smaller reperfusion injury and infarct size at 40 and 60 min approaching steady-state at 90 min after reperfusion. Consistent with a lower injury in air, mitochondrial ROS production by stimulating complex I was much smaller in air-maintained than in immersed hearts. We tested whether increased oxygenation of the ventricle heart walls in the immersed heart might be the cause of higher damage. To reduce oxygen, the KH solution was bubbled with N_2 only. In this condition, the cardiac functional recovery was improved, and the infarct size measured at 60 min after reperfusion was reduced. In conclusion, 40 min reperfusion is sufficient to reach a steady-state infarct size when the hearts are immersed in KH during ischemia, while longer reperfusion time is required if the hearts kept in air. The injury installation during the reperfusion depends on the oxygen surrounding the heart during ischemia. Supported by NIH and AHA.
